ABSTRACT CARDS

PURPOSE:

The purpose of this contract is to provide a substantially improved low temperature Alkaline-MnO₂ primary cell over the best existing commercial product, having significantly improved capacity performance at high rates. The cell shall also have design parameters optimized in all areas of performance and shall possess a high level of reliability.

In addition, the following conditions of shelf and service maintenance are to be met.

70% of 70°F. capacity after:

- A. 12 months storage at 113°F.
- B. 3 months storage at 130°F.
- C. 1 month storage at 160°F.

Seal improvement to provide a high degree of resistance to electrolyte leakage. The above will all be adaptable to a wide variety of sizes and shapes.

ABSTRACT:

This First Quarterly Report covers the initial effort to analyze the present factory product E-95 (D size) Alkaline-MnO₂ round cell with special emphasis placed on location of problem areas affecting low temperature, heavy drain service. In addition based on the above analysis empirical data was obtained from variations of electrode and electrolyte formulations as well as separator materials. From the above work, an optimized cell has been obtained for use in factory trials. This cell contains a cathode with a 4/1 ore to carbon ratio, an electrolyte with 40% KOH as dispensed into the cell (apporximately 32% equilibrium value in the anolyte), a Viskon-Vinyon separator and a powdered zinc anode. The work to date has indicated a need for a higher surface area zinc. In addition, more work to perfect the seal is needed.

Uniformity of cathode mix formulations will also be characterized with respect to solution volumes, packing, density, etc.

CONFERENCES:

1. May 18, 1962 at Fort Monmouth, New Jersey, to discuss work plans.

FACTUAL DATA:

The work done in the first quarter of the contract was divided into two categories, namely:

- 1. Present E-95 cell analysis and characterization.
- 2. Substitution of various materials and electrode formulations in "D" size alkaline cells (E-95).

The goal for this quarter was to establish one or two cell models suitable for factory trials. The above categories of work were accomplished simultaneously and much information was relatable in both areas.

The following topics are a detailed account of the work done. Data and curves for these topics are presented in the Figures and Tables at the end of the text.

FACTORY PRODUCT E-95 CELL ANALYSIS.

This portion of the work consisted mainly of cell testing with the aid of reference electrodes and interrupted current techniques (Kordesch Sine Wave Apparatus) (Ref. K. Kordesch, Battery Conference of SCEL, May, 1955.) to determine gross factors affecting I.R. drop and polarization in the cell. For this use, three month old E-95 factory product cells were tested.

The reference electrode used was a zinc wire, polished with fine emery cloth, wrapped with two wraps of Viskon-Vinyon separator material and sealed at both ends to the wire by asphalt. The reference electrode was dipped in H₂O and then 45.2% KOH prior to insertion into the anode cavity of the E-95 cell (Figure 1)

Work reported was done on a sine wave pulser.

An oscilloscope was used to measure IR drops in each electrode. A vacuum tube voltmeter was used to measure open circuit (OCV) and closed circuit potentials (CCV) at each electrode with respect to a zinc reference wire. Since the scope measured only the voltage drop from open circuit to closed circuit associated with the <u>peak</u> pulse current, a VTVM was used to measure absolute voltages (OCV and CCV) associated with an <u>average</u> pulse current. (Figure 2) The average pulse current was read on an ammeter and the pulse current was calculated from the ammeter value by the relation:

Pulse Current = (π) X (Ave. Current).

Resistance values were calculated by the following relations:

It was obvious that the resistance value was dependent on the accuracy of the average current reading. Since this was the case, resistance values were not calculated; instead percentages of total cell IR drop were calculated for each electrode by the relation:

% Cathode IR = CR (IR of Cathode to Ref. from Oscilloscope)
AC (IR of Anode to Cathode from Oscilloscope)

The accuracy to which each IR loss was determined was within 10% of the estimated true value.

Testing three months old factory product cells at 70°F., 0°F., and -40°F. has shown that the per cent anode IR loss was increasingly greater with decreasing temperatures. The percentages for a given temperature were fairly

constant regardless of drain (Table 1). Tables 2 and 3 show full discharges at 0°F, and -40°F, and the values were consistant with Table 1.

It is not yet known how these relationships hold with cell age or mix formulation. It was apparent, however, that the cathode provided a fertile area for reduction of IR losses and, in fact, later testing of fresh development cells showed the cathode IR losses were as much as 80% of the total cell IR losses. Work will, of course, continue in this area with our best model cells.

Factory product cell testing by conventional techniques across fixed resistors at a variety of loads and temperatures has shown the following characterization. (Tables 4 and 13)

		% Room	Temperature	Service
Temp.	Load	1.0 V.	0.9 V.	0.8 V.
0°F.	1.0 ohm	3.5	5.6	8.2
	2.25 "	7.5	13.3	17.0
	10.0 "	27.6	39.6	48.7
-40°F.	2.25 ohm	1.6	2.2	3.2
	4.0 "	1.9*	3.5	5.3
	10.0 "	9.4	11.0	17.8

*Estimated from Table 13 data.

It can be seen that there is a good deal of service available at the lower voltage cutoffs on fairly heavy drains (2.25 and 4.0 ohm continuous). It is also seen that service decreases with decreasing temperature and increases with decreasing drain.

Intermittent service and delayed testing have not as yet been done.

Gains in service through intermittent discharge are no doubt possible. Simulated

BA - "A" section drains will be part of the future test schedule also.

CATHODE VARIATIONS.

Initial screening was done by varying cathode wall thicknesses and ore to carbon ratios in order to reduce cathode resistance.

Tables 5 and 14 show the effects from proceeding from 11.8/1 to 4/1 ore to carbon ratios. Definite improvements exist in going to 4/1 ore to carbon formulations on both 2.25 and 4.0 ohm tests. In addition, use of Air Spun Graphite (ASG) as sole conductor showed quite another improvement; however, the result was not entirely reproducible. (Figures 3 and 4)

Additional cell making and testing (Tables 6 and 14) confirmed the advantage of 4/1 ore to carbon ratio mixes over control.

Electrode thickness affected each formulation differently. 0.920 ID cathodes (approximately 0.160 inch thick electrodes) were best for 4/1 mixes. (Table 14) (Figure 5)

The most outstanding problem with the cell was uniformity of service levels from lot to lot with a given mix formulation. This was also true with the control product as shown in Table 13. Although substantial improvements have been made to high voltage cuts on heavy drains at -40°F., the level of service is not uniform for these conditions. This is partially a function of the limited (1.0-5.0%) capacity withdrawn to 1.0 volt and the differences in cell to cell IR values. Both of these factors even out as the cell approaches the lower (0.8 volt - 0.6 volt) but still usable cutoffs during heavy drain, low temperature discharge. (Tables 13, 14, 16)

It is not known what effect lighter drains, cell age or intermittancy of discharge have on the above situation.

This effect is within the performance range of present dry battery service variation under the same conditions. One factor affecting uniformity

of service was cathode mix moisture content (Fig. 6). Cathode density as well as electrolyte wetting are both affected by mix moisture. (Table 14, Lots 55, 59, 60)

Factors which affect uniformity are as follows:

- 1. Cathode density related to conductivity.
- 2. Cathode wetting availability of liquid at reaction sites.
- 3. Raw material uniformity with respect to:
 - a. Moisture content.
 - b. Particle size distribution.
- 4. Proper mixing of formulations.

Comparative cell analysis with the aid of zinc reference electrodes and the Kordesch Sine Wave Apparatus further confirm the advantage of the 4/1 ore to carbon cathodes over control. (Figures 11A, 11B, 11C, 11D) Figure 11A shows the terminal cell voltages during the 0.250 amp (approximate) average discharge (0.785 amp pulsed, 1/2 time discharged). It can be seen that the 4/1 ore to carbon cathodes display higher discharge curves than control. (Readings taken with VTVM) Figure 11B shows the IR free discharges for these same cells. Here, again, the 4/1 cathodes demonstrate superior discharge curves. Since the IR free curves are a measure of cell polarization, it is apparent that in addition to reducing IR losses the 4/1 cathodes also demonstrate reduced cathode polarization. Figures 11C and 11D compare cell IR losses (Figure 11C) with cathode IR losses (Figure 11D) for these same cells. It is clear that the reduction in cell IR losses with the 4/1 ore to carbon cathodes vs. control is almost entirely due to reduction in cathode IR.

Areas for future cathode work are:

1. Establishing the parameters affecting service uniformity at -40°F. temperature.

- 2. Determination of best possible conductor or conductor combination.
- Improvement of mixing operation through use of mullor-type mixing, if possible.
- 4. Establishing raw material specifications for more uniform electrode fabrication.
- 5. Determining a more precise measurement of moisture content.
- 6. Establish the effect of cell age prior to testing.

ELECTROLYTE VARIATIONS.

Work in this area (Tables 8 and 15) was centered around providing the correct electrolyte concentration for -40°F. performance by direct substitution into cells. All electrolyte concentrations were given as the concentration of the liquid being dispensed. From the table, it is apparent that between 37 and 40.5% KOH was the optimum value for balancing conductivity, eutectic and KOH availability.

Since the factory product is now 40.5%, it is felt that no large advantage is gained by going lower.

Other substitutions involved the use of Na₂SiO₃·5H₂O as a sequestering agent to limit the hydroxide reaction and promote the zincate reaction. It was hoped that this would provide a clean zinc surface. No elaborate trial of this material was attempted; therefore, no conclusions can be drawn other than the fact that the amount used gave 50% of control service to 0.9 V. on 4 ohm tests at -40°F. (The above general conclusions apply also to the use of Li(OH) in the electrolyte.)

ZINC VARIATIONS.

No full scale attempt has been made to correlate zinc surface area (particle size distribution) with cell performance at -40°F. The small amount of work done, however, has shown particle size to be a factor on IR losses to the high voltage cutoffs. It is expected that a higher surface area zinc would reduce anode polarization also.

Tables 9 and 16 show that screening of RM-976 zinc powder to various fractions has yielded as much as 150% of control service at -40°F, with the finer zincs. Figures 12A, 12B, and 12C demonstrate the effects of fine zinc by the use of the Kordesch sine wave, interrupted current technique. Cell closed circuit voltages (CCV) vs. cell IR free voltages (OCV) show decreases in cell IR and polarization (Figure 12B) with the use of finer zinces. Figure 12C shows that the cathode IR for the control lot 61 and the fine zinc lot 62 was essentially the same, therefore, improvements in total cell IR and polarization must be related to the finer zinc. Finer zincs possibly may show higher gassing rates on high temperature shelf. Future areas of work will be with various forms of zinc (fibre, foam, etc.), uniformity control of RM-976 zinc or fractions thereof (Fig. 13) and their effect on low temperature service and high temperature shelf.

ANODE COLLECTOR VARIATIONS.

Efforts to improve the particle to particle contact of the anode by restricting the space available for the paste anode expansion have demonstrated that no improvement can be expected in this area of approach. Although 70°F. flash current was improved, the -40°F. service was reduced by reducing the total anode surface exposed to electrolyte and by blocking the paths for electrolyte migration (Table 17).

SEPARATOR VARIATIONS. (Table 18)

Only limited work was done in this area to ascertain the effects of multiple wraps of Viskon-Vinyon on -40°F. service. Based on past data, use of two wraps of Viskon-Vinyon provides adequate shelf stability, as well as acceptable service performance. It is felt that more uniform, better wetting, thinner materials would contribute to lower IR losses. Work will continue in the area of other material substitutions.

Use of cellophane (LSD-195) indicated 67% of control performance on 4 ohm -40°F. service to 1.0 volt, however, it is not known whether this is due to the increased numbers of wraps (4) versus control (2) or the properties of cellophane.

GENERAL.

Typical curves of all the above variations are shown in the Appendix. In addition, curves showing IR losses by sine wave current techniques with 4/1 ore to carbon ratio cathodes are also in the Appendix.

SEAL.

Work is in progress to improve the reliability of the nylon seal so as to meet the requirements of high temperature shelf performance.

CONCLUSIONS:

I. Electrode analysis with reference cells and interrupted sinusoidal current techniques has shown the following on 3 month old factory product cells.

	Per Cent of Total Cel	l Internal Resistance
	% of Cell IR	% of Cell IR
Temp.	Due to Cathode	Due to Anode
70°F.	95-97	3-5
O°F.	70-80	20-30
-40°F.	50-70	30-50

Cathode factors play a dominant part in cell IR losses. However, the anode contributes increasingly at the lower temperatures to these losses.

Effects of separator contribution or cell age to IR losses have not been fully determined.

II. Factory Product characterization on 3 month old cells has shown the following. (Table 4)

		Pe:	c Cent of	Room	Temp.	Service	
		-40°F.				O°F.	
Load	1.0 V.	0.9 V.	0.8 V.		1.0 V.	0.9 V.	0.8 V.
1.0 ohm	-	-	•		3.5	5.6	8.2
2.25 "	1.6	2.2	3.2		7.5	13.3	17.0
4.0 "	1.9*	3.5	5.3		-	•	•
10.0 "	9.4	11.0	17.8		27.8	39.6	48.7

*Estimated from Table 13 data.

Thus it can be seen that considerable service is available to the lower voltage cutoffs at low temperatures, and that efficiency increases with decreasing drain and increasing temperature.

III. Formulating with varying ore to carbon ratios from 11.8/1 to 4/1 has shown that the more conductive 4/1 mixes (control = 5/1) offer between 50% and

- 100% improvement to 1.0 volt service at -40°F. (2.25 and 4.0 ohm loads) while maintaining the same extended low voltage service as control.

 (Table 5)
- IV. Varying cathode wall thicknesses from 0.175 to 0.145 has shown 0.160 inch thick electrodes to be optimum for 4/1 ore to carbon mixes. This corresponds to a 0.920 O.D. cathode molding ram. (Table 5)
- V. Additional work is needed to determine which conductor or mixture of conductors is best. Use of air spun graphite as sole conductor or mixtures of acetylene black and #2624 graphite have shown essentially equivalent results in 4/1 ore to carbon ratio mixes.
- VI. The electrolyte concentration should be 40% KOH prior to dispensing in the cell. This is approximately a 31-33% equilibrium value when mixed with the other analyte ingredients. (Table 15)
- VII. Use of finer powdered zincs with better control of particle size distribution shows indications of improving low temperature performance. It has not as yet been determined what effect this will have on high temperature shelf maintenance. (Table 16)
- VIII. Two wraps of Viskon-Vinyon separator material (approx. .008 inch/wrap) are optimum for overall cell performance. (Table 18)
- IX. Although substantial improvements have been made to high voltage cuts on heavy drains at -40°F. the level of service is not uniform for these conditions. This is partially a function of the limited (1.0-5.0%) capacity withdrawn to 1.0 volt and the differences in cell to cell IR values.

 Both of these factors even out as the cell approaches the lower (0.8 0.6 volt) but still usable cutoffs during heavy drain, low temperature discharge. (Tables 13, 14, 16)

It is not known what effect lighter drains, cell age, or intermittency of discharge have on the above situation. This non-uniformity effect is within the performance range of present day dry battery service variation under the same conditions.

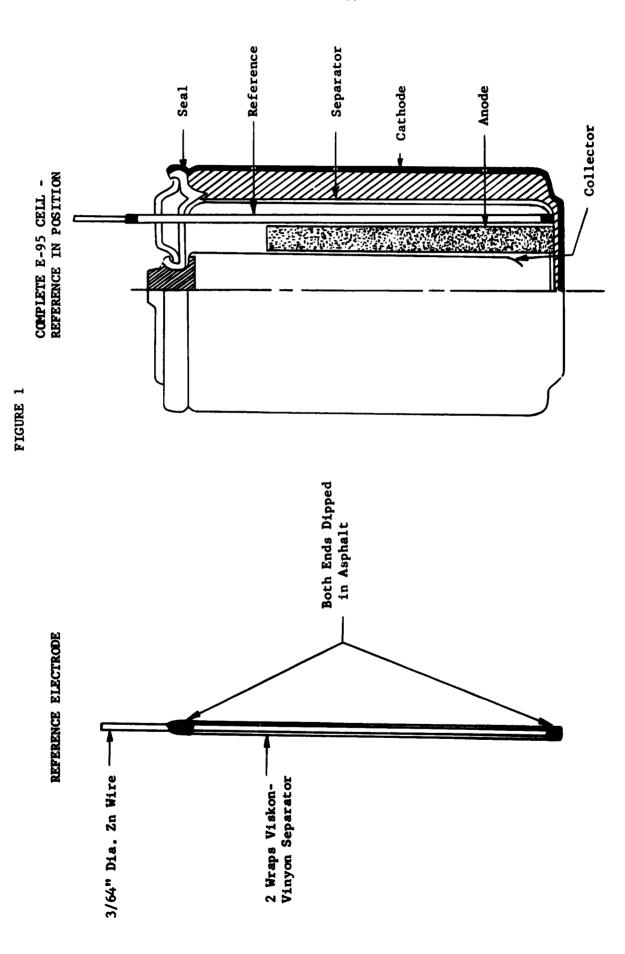

FUTURE WORK OUTLINE:

In the next quarter, the following work will be done:

- 1. Establishment of final cathode formulations.
- 2. Resolution within the limits of the contract those parameters affecting uniformity of service levels.
- 3. Finalized seal configuration to meet contract requirements.
- 4. Investigation of various separator materials.
- 5. Investigation of various zinc anode forms and/or powdered zinc fractions best suited for low temperatures and high temperatures.
- 6. Factory trial of best model with subsequent characterization.
